

USE OF A DIOPHANTINE EQUATION TO FACTOR ANY SEMI-PRIME

Several years ago we showed on this web page how one can factor the semi-prime $N=pq$ using the equation-

$$[p,q]=S-\sqrt{S^2-N}$$

, where $S=(p+q)/2=(\sigma(N)-N-1)/2$ and $\sigma(N)$ is the sigma function of number theory.

The approach works well as long as $N=pq$ is less than about forty digits long. Within this limit the advanced math programs Mathematica or Maple yield closed form values for $\sigma(N)$. For N s in excess of these lengths the finding of $\sigma(N)$ becomes cumbersome and thus impractical for still larger semi-primes such as the ones encountered in cyber-security. We wish here to extend the factoring process to large semi-primes by a new technique involving a new function x heretofore recognized.

We start by noting that if $p=q$, then both primes equal \sqrt{N} . Since both p and q are odd integers \sqrt{N} must be modified to integer form. We let-

$$R = \text{nearest integer above } \sqrt{N}$$

This suggests the new definition-

$$2(R+x)=p+N/p$$

On rewriting we get-

$$p^2-2p(R+x)+N=0$$

On solving we have-

$$p=(R+x)-\sqrt{(R+x)^2-N}$$

For p to be integer as well as x and R , we arrive at the new non-linear Diophantine equation-

$$(R+x)^2-N=y^2$$

, with y also a positive integer. Once this has been solved by the one line program-

```
for x from 0 to b do({x,sqrt((x+R)^2-N)})od
```

we can recover both p and q at once. Typically, when x is an integer a lot smaller than R , there will be only a small number of trials involved in finding both integer x and y . When x gets larger it is best to use the re-written Diophantine form-

$$y^2=(R^2-N)+2xR+x^2$$

and to note that typically $2xR$ is large compared to both (R^2-N) and x^2 . So that y^2 equals an integer a little above $2xR$.

Let us demonstrate the new factoring approach with $N=2201$ where $R=47$. Solving we find $[x, y]=[4, 20]$. So $p=(R+x-y)=31$ and $q=N/p=71$. The speed with which the result was obtained is impressive requiring only four trails.

Take next the larger six digit long semi-prime $N=455839$. Here $R=676$. Running the program from $x=0$ to $x=8$ we obtain the following table-

FACTORING OF N=455839

```
for x from -1 to 8 do ((x, sqrt((676+x)^2-455839)))od;
```

$(-1, i\sqrt{214})$
$(0, \sqrt{1137})$
$(1, \sqrt{2490})$
$(2, \sqrt{3845})$
$(3, 51\sqrt{2})$
$(4, 81)$
$(5, \sqrt{7922})$
$(6, \sqrt{9285})$
$(7, 5\sqrt{426})$
$(8, \sqrt{12017})$

$P=R+x-y=599$
 $q=N/p=761$

$x=4, y=81$

This result can also be obtained by the Lenstra elliptic curve method but only for at a considerable amount of extra work.

Finally let us consider the nine digit long semi-prime-

$$N:=137703491 \quad \text{where} \quad R=11735$$

Here it takes a total of 919 trials, starting with $x=1$, to arrive at $[x,y]=[919, 4735]$. From this solution we deduce that-

$$p=R+x-y=7919 \quad \text{and} \quad q=N/p=17389$$

Notice the rapid increase in the value of x as N gets larger than about eight digits. Under those conditions it might be a good idea to start the search at $x=0.1 \cdot R=1174$ and then search in the neighborhood. At trial $x=-255$ you will find your answer.

We have shown that the semi-prime $N=pq$ can be factored into its two prime components by solving the Diophantine Equation $(R+x)^2-N=y^2$, where R is the first integer value above \sqrt{N} . Once the integer values of $[x,y]$ have been found, the values of p and q follow from-

$$p=(R+x)-y \quad \text{and} \quad q=N/p \quad \text{with } p < q$$

The value of x increases with increasing N but typically stays below about ten percent of R .
